

9. Additional topics in linear modeling

Outline

- We now have practical skills to
 - ① Write down linear models,
 - ② Fit them in R,
 - ③ Interpret the output in terms of parameter estimates, confidence intervals and hypothesis tests,
 - ④ Check that R is fitting the model that we intend,
 - ⑤ Check that the model we intend is appropriate for the data.
- These skills provide a foundation for many extensions helpful for particular situations.

Topics

- More on the linear model formula notation in R.
- Interactions between explanatory variables.
- The R^2 statistic to assess model fit.
- Fitting polynomial relationships using linear models.
- Multicollinearity: What happens when two or more explanatory variables are highly correlated. How to notice it, and what to do about it.
- Power: What is the probability of rejecting the null hypothesis when the alternative is true?

The R model formula notation

- A **model formula** in `lm()` is something that looks like $y \sim x$.
- The R formula notation has various conventions that are designed to make it easy to specify useful models.
- `?formula` tells you everything you need to know, and more.
- You can think of the R formula for `lm()` is a way of constructing a design matrix.
- Inspect the resulting design matrix using `model.matrix()` and check you understand what R has produced. If you can do this, you can safely use the power of the formula notation.

Question 9.1. In a report, the model should be written in mathematical notation, not as an R formula. Why?

todo

Experimenting with the R formula notation

- Consider the freshman GPA data

```
gpa <- read.table("gpa.txt",header=T); head(gpa,3)
##   ID  GPA High_School ACT Year
## 1   1 0.98          61  20 1996
## 2   2 1.13          84  20 1996
## 3   3 1.25          74  19 1996
```

- We can play the game of trying out various things in R formula notation, inspecting the resulting design matrix, and figuring out how to write the model efficiently in mathematical notation.
- You can also think about whether the different models give any new insights into the data.

```
lm1 <- lm(GPA~ACT+High_School*Year,data=gpa)
coef(summary(lm1))[,1:2]
```

##	Estimate	Std. Error
## (Intercept)	-4.722613e+01	1.350854e+02
## ACT	3.708961e-02	5.946966e-03
## High_School	3.460100e-01	1.702035e+00
## Year	2.428369e-02	6.760800e-02
## High_School:Year	-1.681424e-04	8.518297e-04

- The * here denotes inclusion of an **interaction** between High_School and Year, written in the R output as High_School:Year.

Question 9.2. Conceptually, what do you think an interaction between two variables is, and why might it be needed?

todo

- To find out exactly what R thinks an interaction is, we can check the design matrix.

```
head(model.matrix(lm1))
```

```
##      (Intercept) ACT High_School Year High_School:Year
## 1              1  20              61 1996              121756
## 2              1  20              84 1996              167664
## 3              1  19              74 1996              147704
## 4              1  23              95 1996              189620
## 5              1  28              77 1996              153692
## 6              1  23              47 1996              93812
```

Question 9.3. Write out the sample model that R has computed in `lm1` using subscript notation.

todo

Interactions and additivity

```
lm2 <- lm(GPA~ACT+High_School+Year+High_School:Year,data=gpa)
head(model.matrix(lm2),4)
```

##	(Intercept)	ACT	High_School	Year	High_School:Year
## 1	1	20	61	1996	121756
## 2	1	20	84	1996	167664
## 3	1	19	74	1996	147704
## 4	1	23	95	1996	189620

- `lm2` has the same design matrix as `lm1`.
- We see that, in R formula notation, $y \sim u * v$ is the same as $y \sim u + v + u : v$.
- In the model $y \sim u + v$ the effects of the variables are said to be **additive**.
- In a causal interpretation of an additive model, the result of changing u to u_2 and v to v_2 is the sum of the marginal effect of changing u to u_2 plus the marginal effect of changing v to v_2 .
- The interaction term $u : v$ breaks additivity. In this case, we can't know the consequence for the fitted value of changing u to u_2 unless we know

The interaction between ACT and high school percentile

- We have not (yet) found any interesting effect of year. Let's drop year out of the model and look for whether there is an interaction between ACT and high school percentile for predicting freshman GPA.

```
lm3 <- lm(GPA~ACT*High_School, data=gpa)
```

Question 9.4. Write out the fitted sample linear model in subscript form, letting y_i , a_i , h_i and e_i be the freshman GPA, ACT score, high school percentile and residual error respectively for the i th student.

todo

Interpreting a discovered interaction

```
coef(summary(lm3))[,1:2]
```

##	Estimate	Std. Error
## (Intercept)	3.157679842	0.4788067771
## ACT	-0.046067744	0.0213355076
## High_School	-0.014405030	0.0061479608
## ACT:High_School	0.001071326	0.0002638611

Question 9.5. Explain in words to the admissions director what you have found about the interaction under investigation here.

todo

Marginal effects when there is an interaction

- Notice in 'lm3' that the coefficients for ACT score and high school percentile are negative. That is surprising!

```
ACT_centered <- gpa$ACT - mean(gpa$ACT)
HS_centered <- gpa$Hi - mean(gpa$Hi)
lm3b <- lm(GPA ~ ACT_centered * HS_centered, data = gpa)
signif(coef(summary(lm3b))[, c(1, 2, 4)], 3)
```

##	Estimate	Std. Error	Pr(> t)
## (Intercept)	2.94000	0.022900	0.00e+00
## ACT_centered	0.03640	0.005880	1.04e-09
## HS_centered	0.01190	0.001350	8.23e-18
## ACT_centered:HS_centered	0.00107	0.000264	5.46e-05

Question 9.6. After centering the variables, the interaction effect stays the same, but the marginal effects change sign. What is happening? Why?

todo

Quantifying the improvement in the model

```
s3 <- summary(lm3)$sigma
lm4 <- lm(GPA~ACT+High_School,data=gpa)
s4 <- summary(lm4)$sigma
lm5 <- lm(GPA~1,data=gpa)
s5 <- summary(lm5)$sigma
cat("s3 =",s3,"; s4 =",s4,"; s5 =",s5)

## s3 = 0.5610067 ; s4 = 0.5671605 ; s5 = 0.6345278
```

Question 9.7. Comment on both **statistical significance** and **practical significance** of the interaction between a prediction of freshman GPA.

todo

An interaction involving a factor

- Let's go back to the football field goal data.

```
goals <- read.table("FieldGoals2003to2006.csv",header=T,sep=",")
goals[1,c("Name","Teamt","FGt","FGtM1")]
```

```
##           Name Teamt  FGt FGtM1
## 1 Adam Vinatieri    NE 73.5    90
```

```
lm6 <- lm(FGt~FGtM1*Name,data=goals)
```

Question 9.8. What model do you think is being fitted here? Write it in subscript form, where y_{ij} is the field goal average for the j th year of kicker i , with $i = 1, \dots, 19$ and $j = 1, 2, 3, 4$. Let e_{ij} be the residual error, and let x_{ij} be the previous year's average. Check your answer against the design matrix shown on the next slide.

todo

```
X<-model.matrix(lm6) ; colnames(X)<-1:38 ; X[1:17,c(1:8,21:26)]
```

##		1	2	3	4	5	6	7	8	21	22	23	24	25	26
## 1	1	90.0	0	0	0	0	0	0	0	0.0	0.0	0.0	0	0	0
## 2	1	73.5	0	0	0	0	0	0	0	0.0	0.0	0.0	0	0	0

```

Collinear explanatory variables in a linear model

- Let $\mathbb{X} = [x_{ij}]_{n \times p}$ be an $n \times p$ design matrix.
- If there is a nonzero vector $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_p)$ such that $\mathbb{X}\boldsymbol{\alpha} = \mathbf{0}$ then the columns of \mathbb{X} are **collinear**.
- Here, $\mathbf{0}$ is the zero vector, $(0, 0, \dots, 0)$.
- We can write $\mathbf{x}_j = (x_{1j}, x_{2j}, \dots, x_{nj})$ for the j th column of \mathbb{X} . Then,

$$\mathbb{X}\boldsymbol{\alpha} = \alpha_1\mathbf{x}_1 + \alpha_2\mathbf{x}_2 + \dots + \alpha_p\mathbf{x}_p.$$

We see that $\mathbb{X}\boldsymbol{\alpha}$ can be thought of as a **linear combination of the columns of \mathbb{X}** .

- Collinearity of explanatory variables has important consequences for fitting a linear model to data.
- It can also be useful to notice whether the variables are close to collinear, meaning that $\mathbb{X}\boldsymbol{\alpha}$ is small but nonzero.

Example: an intercept with a coefficient for each factor

- Recall the mouse weight dataset. Consider a sample linear model,

$$y_{ij} = \mu + \mu_j + e_{ij}.$$

- Suppose that we don't set the $\mu_1 = 0$ so we try to estimate both μ_1 and μ_2 at the same time as the intercept, μ .
- Let's work with just 3 mice in each treatment group, so $i = 1, 2, 3$ and $j = 1, 2$. The design matrix is therefore

```
X <- cbind(rep(1,6),rep(c(1,0),each=3),rep(c(0,1),each=3)) ; X
##      [,1] [,2] [,3]
## [1,]    1    1    0
## [2,]    1    1    0
## [3,]    1    1    0
## [4,]    1    0    1
## [5,]    1    0    1
## [6,]    1    0    1
```

- For $\alpha = (1, -1, -1)$, we have $\mathbb{X}\alpha = 0$

The least squares fit with collinear predictors

- Suppose that \mathbf{b} is a least squares coefficient vector, so that the fitted value vector $\hat{\mathbf{y}} = \mathbb{X}\mathbf{b}$ minimizes $\sum_{i=1}^n (y_i - \hat{y}_i)^2$.
- Suppose that \mathbb{X} is collinear, with $\mathbb{X}\boldsymbol{\alpha} = \mathbf{0}$.
- Since

$$\mathbb{X}(\mathbf{b} + \boldsymbol{\alpha}) = \mathbb{X}\mathbf{b} + \mathbb{X}\boldsymbol{\alpha} = \mathbb{X}\mathbf{b} + \mathbf{0} = \mathbb{X}\mathbf{b},$$

we see that $\mathbf{b} + \boldsymbol{\alpha}$ is also a least squares coefficient vector.

- **When \mathbb{X} is collinear, a least squares coefficient still exists, but it is not unique.**

Question 9.10. Let c be any number. Recall multiplication of a vector by a scalar: $c\boldsymbol{\alpha} = (c\alpha_1, \dots, c\alpha_p)$. Show that $\mathbf{b} + c\boldsymbol{\alpha}$ is also a least squares fit.

Standard errors for collinear variables

Question 9.11. Any variable that is part of a collinear combination of variables has infinite standard error. Why?

todo

What does R do if give it collinear variables?

```
mice <- read.table("femaleMiceWeights.csv",header=T,sep=",")
chow=rep(c(1,0),each=12)
hf=rep(c(0,1),each=12)
lm1 <- lm(Bodyweight~chow+hf,data=mice)
coef(summary(lm1))
```

	Estimate	Std. Error	t value	Pr(> t)
## (Intercept)	26.834167	1.039353	25.818139	6.045435e-18
## chow	-3.020833	1.469867	-2.055174	5.192480e-02

- R noticed that the three explanatory variables are collinear, and refused to fit the third

```
model.matrix(lm1)
```

##	(Intercept)	chow	hf
## 1	1	1	0
## 2	1	1	0
## 3	1	1	0
## 4	1	1	0
## 5	1	1	0
## 6	1	1	0
## 7	1	1	0
## 8	1	1	0
## 9	1	1	0
## 10	1	1	0
## 11	1	1	0
## 12	1	1	0
## 13	1	0	1
## 14	1	0	1
## 15	1	0	1
## 16	1	0	1
## 17	1	0	1
## 18	1	0	1
## 19	1	0	1

Linearly independent vectors and matrix rank

- Columns of a matrix that are not collinear are said to be **linearly independent**.
- The **rank** of \mathbf{X} is the number of linearly independent columns.
- \mathbf{X} has **full rank** if all the columns are linearly independent. In this case, we expect the least squares coefficient to be uniquely defined and so $\mathbf{X}^T \mathbf{X}$ has non-zero determinant and is invertible.
- If \mathbf{X} does not have full rank, we can drop **linearly dependent** columns until the remaining columns are linearly independent. This is a practical approach to handling collinearity.

Example: reducing a design matrix to full rank

```
X <- model.matrix(lm1)
```

```
det(t(X)%*%X)
```

```
## [1] 0
```

```
X2 <- X[,1:2]
```

```
det(t(X2)%*%X2)
```

```
## [1] 144
```

- Dropping the third column of X has given us a full-rank design matrix.

Question 9.12. The least squares fitted values are the same using the predictor matrix X_2 as X . Why does dropping the last column not change the fitted values?

todo

Almost collinear variables

- If the determinant of $\mathbf{X}^T \mathbf{X}$ is close to zero, the variance of the model-generated least squares coefficient vector becomes large.
- This can happen when multiple explanatory variables are included in a model which all model similar things.

Question 9.13. Recall our data analysis using unemployment to explain life expectancy. What would happen if we added total employment as an additional explanatory variable? (Being unemployed is not the only alternative to being employed, since only adults currently looking for work are counted as unemployed.)

todo

Using linear models to fit polynomial relationships

- Recall the basic linear trend model from Chapter 1 for data y_1, \dots, y_n with y_i measured at time t_i ,

$$[\text{M1}] \quad y_i = b_0 + b_1 t_i + e_i, \quad i = 1, \dots, n$$

- What if the data have a trend that is not linear?
- The next thing we might consider is a quadratic trend model,

$$[\text{M2}] \quad y_i = b_0 + b_1 t_i + b_2 t_i^2 + e_i, \quad i = 1, \dots, n$$

- M1 and M2 are both linear models, with respective design matrices

$$\mathbb{X}^{[1]} = \begin{bmatrix} 1 & t_1 \\ 1 & t_2 \\ \vdots & \vdots \\ 1 & t_n \end{bmatrix} \quad \mathbb{X}^{[2]} = \begin{bmatrix} 1 & t_1 & t_1^2 \\ 1 & t_2 & t_2^2 \\ \vdots & \vdots & \vdots \\ 1 & t_n & t_n^2 \end{bmatrix}$$

The order p polynomial smoothing model

- When the explanatory variable for y_i is the time of measurement, t_i , then we call the linear model a trend.
 - When we fit y_i using a function of an arbitrary explanatory variable x_i we say we are **smoothing**.
 - We can choose any p in the general order p polynomial smoothing model,
- [M3] $y_i = b_0 + b_1x_i + b_2x_i^2 + b_3x_i^3 + \cdots + b_px_i^p + e_i, \quad i = 1, \dots, n$
- This is a linear model with design matrix

$$\mathbb{X}^{[3]} = \begin{bmatrix} 1 & x_1 & x_1^2 & \cdots & x_1^p \\ 1 & x_2 & x_2^2 & \cdots & x_2^p \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_n & x_n^2 & \cdots & x_n^p \end{bmatrix}$$

Question 9.14. How would you decide what order p to use for the polynomial smoothing?

todo

Cubic polynomial smoothing of life expectancy

```
L_poly3 <- lm(Total~Year+I(Year^2)+I(Year^3),data=L)
```

```
plot(L$Year,L$Total,  
     type="line",  
     xlab="Year",  
     ylab="Life expectancy")  
  
lines(L$Year,fitted(L_poly3),  
      lty="dashed")
```

Question 9.15. Why do we need to write $I(\text{Year}^2)$ not just Year^2 to fit a polynomial smoothing model in the R formula notation?

todo

Checking the cubic smoothing calculation

Question 9.16. How would you check that the R model formula we wrote is correct for the cubic polynomial we intend to fit?

todo

Question 9.17. If we have done a good job of modeling the trend, we might hope that the residuals look like independent measurement errors. How would you check if this is the case?

todo

Repeating diagnostic tests for life expectancy vs unemployment using cubic detrending

```
L_detrended <- L_poly3$residuals
U_annual <- apply(U[,2:13],1,mean)
U_detrended <- lm(U_annual~Year+I(Year^2)+I(Year^3),
  data=U)$residuals
L_detrended <- subset(L_detrended,L$Year %in% U$Year)
lm_poly3 <- lm(L_detrended~U_detrended)
n <- length(resid(lm_poly3))
e <- resid(lm_poly3)[2:n] ; lag_e <- resid(lm_poly3)[1:(n-1)]
```

```
plot(U$Year,resid(lm_poly3))
```

```
plot(lag_e,e)
```

Local linear smoothing of life expectancy

```
L_loess <- loess(Total~Year,data=L,span=0.3)
```

```
plot(L$Year,L$Total,  
     type="line",  
     xlab="Year",  
     ylab="Life expectancy")  
  
lines(L$Year,fitted(L_loess),  
      lty="dashed",col="red")
```

- `loess()` is a **smoother** that fits a local linear model. This means that, at each point x_j , the smoother predicts y_i fitting a linear model that ignores all the data except for points close to x_i .
- Setting `span=0.3` means that the closest 30% of the points are used.

Repeating diagnostic tests for life expectancy vs unemployment using a smoother

```
L_detrended <- resid(L_loess)
U_annual <- apply(U[,2:13],1,mean)
U_detrended <- resid(loess(U_annual~Year,data=U,span=0.3))
L_detrended <- subset(L_detrended,L$Year %in% U$Year)
lm_loess <- lm(L_detrended~U_detrended)
n <- length(resid(lm_loess))
e <- resid(lm_loess)[2:n] ; lag_e <- resid(lm_loess)[1:(n-1)]
```

```
plot(U$Year,resid(lm_loess))
```

```
plot(lag_e,e)
```

Revisiting the evidence for pro-cyclical mortality

```
coef(summary(lm_loess))
```

```
##              Estimate Std. Error   t value    Pr(>|t|)
## (Intercept) 0.007138079 0.01613621 0.4423641 0.6596720450
## U_detrended 0.067235405 0.01628394 4.1289394 0.0001045733
```

- Recall that linear detrending gave a significant association between life expectancy and unemployment.
- This suggested that mortality is **pro-cyclical**, meaning it increases when the business cycles is in economic expansion and unemployment is low.
- In Chapter 7, we found the residuals in this regression had a strong pattern, casting doubt on the validity of our linear model and its unintuitive conclusion.

Question 9.18. Re-assess the evidence based on this new analysis.

The R-squared statistics to assess goodness of fit

- R^2 is the square of the correlation between the data and the fitted values.
- It can also be computed as

$$R^2 = 1 - \frac{\text{RSS}}{\text{SST}} = \frac{\text{SST} - \text{RSS}}{\text{SST}}$$

where RSS is the residual sum of squares and SST is the total sum of squares, defined as

$$\text{SST} = \sum_{i=1}^n (y_i - \bar{y})^2, \quad \text{where } \bar{y} = \frac{1}{n} \sum_{i=1}^n y_i.$$

- R^2 is sometimes described as the fraction of the variation in the data explained by the linear model.
- $1 - R^2$ is the fraction of the variation in the data left unexplained by the model.

Uses and abuses of R-squared

- A low R^2 sends a clear signal: the fitted model doesn't describe the data much better than the sample mean.
- Sometimes a small, but statistically significant, correlation is of interest. If you are monitoring data on the operation of an aircraft jet engine, you want to know about evidence suggesting a malfunction as soon as it is statistically significant. **Interpretation of R-squared depends on context.**
- The R^2 statistic compares the residual sum of squares under the full model with the residual sum of squares under a model with a constant mean. By contrast, the F test compares the full model with a model that omits specific selected explanatory variables. The F test is more appropriate for assessing whether a variable, or group of variables, should be included in the model.

A relationship between the F statistic and R-squared

- Recall that in a regression setting, the F statistic is expressed in the following way.

$$f = \frac{(\text{RSS}_0 - \text{RSS}_a)/d}{\text{RSS}_a/(n - q)}.$$

- q is the dimension of the alternative hypothesis.
- d is the difference in dimension between the null and alternative hypotheses.

Question 9.19. Write the hypotheses H_0 and H_a to match the R^2 statistic in a linear model with p explanatory variables (including the intercept). Set up these hypotheses so that RSS_0 is SST , and RSS_a is RSS .

todo

- In this context, we see that $q = p$ and $d = p - 1$.

Writing R^2 in terms of an F statistic

- From last slide, we have

$$f = \frac{(\text{SST} - \text{RSS})/(p - 1)}{\text{RSS}/(n - p)}$$

- Recall that $R^2 = 1 - \text{RSS}/\text{SST}$.

Question 9.20. Check by algebra that $R^2 = 1 - \frac{1}{1 + f \times (p - 1)/(n - p)}$

todo

Question 9.21. What is R^2 when F is very large? or close to zero?

todo

Question 9.22. Explain why R^2 cannot decrease when you add an extra explanatory variable into a linear model. (Explanations for questions like this should involve some math notation, not just words.)

todo

- Simplicity in a model is a good thing. The fact that any added model complexity makes R^2 seem “better” requires caution in interpretation.

Adjusted R-squared

- One approach to penalize R^2 for a more complex model is to divide each sum of squares by its degrees of freedom. This gives the **adjusted R-squared**,

$$R_{\text{adj}}^2 = 1 - \frac{\text{RSS}/(n - p)}{\text{SST}/(n - 1)}.$$

- Dividing by the degrees of freedom in R_{adj}^2 is like what we do in the F statistic.
- The F statistic takes advantage of the nice mathematical property that $\text{SST} - \text{RSS}$ and RSS are independent random variables for the probability model with normally distributed measurement error.
- For comparing two **nested** models (when the larger model consists of adding variables to the smaller model) an F test is a clearer statistical argument than comparing R_{adj}^2 .
- When the models are not nested, the F test is not applicable. Comparing R_{adj}^2 values gives one way to assess the models, though not a formal test.
- Now we've studied R_{adj}^2 , we understand everything in `summary(lm())`.

Model selection

- Suppose we have a large number ℓ of potential explanatory variables in our dataset.
- The total number of possible linear models is 2^ℓ since each of the ℓ variables can be either in or out of the model.
- If we allow for the possibility of interactions, things are even worse.
- For two variables x_{i1} and x_{i2} on each individual $i = 1, 2, \dots, n$, modeling an **interaction** can be viewed as including a new variable $x_{i3} = x_{i1}x_{i2}$.

Question 9.23. If there are ℓ explanatory variables, considered as **main effects**, and any pair of them could give rise to an **interaction effect**, how many possible models are there? For simplicity, allow for the possibility of including interactions without the main effects.

Practical considerations for model selection

- Sometimes, you build models based on specific hypotheses about the system you are investigating.
- In this case, our tools for hypothesis testing work well. You work through a process of starting with a basic model and considering a relatively small sequence of alternative hypotheses to build up an understanding of the data.
- A different scenario occurs when you explore a very large number of different models.
- If you consider 1000 alternative models and each one is tested at significance level 0.01 then you expect to find 10 models that would formally let you reject the null hypothesis at a “high” level of significance for random variables generated under the null model.
- Similar issues arise if you consider many variables in a single linear model and look to identify significant ones.

The expected number of false discoveries

Question 9.24. Suppose that you consider $\ell = 100$ variables by placing them all in a linear model and reporting the variables whose t statistic is significant at the 0.05 level. How many “significant” variables would you expect to report under a null probability model where all the coefficients are zero?

todo

Confidence intervals after model selection

Question 9.25. Suppose you have $\ell = 100$ explanatory variables and you consider $\ell = 100$ different models, each with only one of the explanatory variables in the model. You pick as your favorite model the one with the highest R^2 statistic, which is equivalent to picking the one with the smallest p-value for its t statistic. You report a 95% confidence interval for the coefficient in this linear model. What is the chance that this confidence interval will cover the truth, under the null probability model where all the coefficients for all the explanatory variables are zero?

todo

Dealing with multiple testing

- The difficulty of properly evaluating statistical significance when investigating very many hypotheses is called the **multiple testing** situation.
- Dealing with multiple testing is a current scientific concern. It is related to the so-called crisis in scientific reproducibility.
- Advances in data acquisition and computation increasingly lead to large datasets to be investigated.
- One principle: report all the tests you make, not just the nominally significant ones. This lets the reader assess the hazard of multiple testing bias.
- Another principle: any result not yet confirmed by an independent experiment is suspicious.

The causal interpretation of observational studies

- Consider a simple least-squares linear model $y_i = ax_i + b + e_i$ for $i = 1, \dots, n$. The usual corresponding probability model is $Y_i = \alpha x_i + \beta + \epsilon_i$ with $\epsilon_1, \dots, \epsilon_n$ being independent $N[0, \sigma]$ random variables.
- The coefficient α for x_i , $i = 1, \dots, n$ is commonly called the **effect** of x_i on y_i .
- Sometimes a is called the effect, but it is more properly an **estimated effect**.
- The **causal interpretation** of the linear model is that, if we manipulated x_i to increase it by one unit for individual i , keeping everything else fixed, we would expect y_i to increase by a units.
- The use of the word “effect” has a causal meaning in common usage.
- We should think carefully about when this meaning is justified.

Does coffee cause heart attacks?

- Coffee has relatively high levels of caffeine, a commonly consumed drug. Many studies have been done to see if it has adverse (or positive) health effects.
- A typical observational study will model a health outcome (say, a measure of heart health) and investigate linear models based on available explanatory variables.
- If higher levels of coffee consumption are associated with lower heart health scores, beyond what can be explained by chance variation in our sample, we will be suspicious about drinking coffee.

Question 9.26. Suggest important confounding variable(s) in the causal interpretation of this model. What would you do to help make a convincing argument for or against coffee?

todo

Which surgeon do you choose?

- Cost effectiveness of medical treatment is a major current issue. You are advising a health insurance program, and your boss gives you data on success rates for a certain heart surgery, together with the salary of the surgeon performing the operation.

Question 9.27. Suppose you find the estimated effect is negative and statistically significant: higher salaries are associated with lower success rates. How would you interpret this result? What are possible confounding factors?

todo

When can we infer causation from observational data?

The following considerations may add weight to the causal interpretation of an association

- There is a plausible mechanism.
- There are no un-measured variables considered plausible mechanisms.
- The effect is consistent across population subgroups.
- For data collected though time, the proposed cause precedes the consequence.
- Consistency with available experimental evidence.
- A consistent gradient between increases in the proposed cause and its consequence.

The ideas were developed in the 1950s while tracking down the case against cigarettes (Wikipedia: Bradford Hill criteria) and continue to be debated.

How did the observations get into the study?

- There is risk of **selection bias** if the individuals are not selected randomly from the population they are supposed to represent.
- Selection bias is a type of confounding. The confounder is a variable that explains the selection process.

Question 9.28. In World War II, the US Airforce was suffering heavy losses in bombing raids over Germany. To decide where to add extra armor, engineers studied bullet holes on returning planes to see which parts were exposed to most gunfire. A prominent statistician, Abraham Wald, provided a different interpretation. What was it?

todo

Revisiting the fieldgoal kicker data

- Any observations study can and should be examined for confounding and selection bias issues.

Question 9.29. Consider the field goal percentage data. Recall that we analyzed the 19 NFL kickers who made at least ten field goal attempts in each of 2002, 2003, 2004, 2005 and 2006 seasons. We found a slope of -0.504 when predicting field goal percentage in year t using field goal percentage in year $t-1$, with a separate intercept for each kicker. Comment on the possible roles of selection bias and/or confounding for interpreting this result.

todo

Randomized experiments and random samples

- The huge difficulties interpreting observational studies motivate avoiding them whenever possible
- Random assignment to treatment in a controlled experiment removes the possibility of confounding, and ensures that any statistically significant effect can legitimately be given a causal interpretation.
- A **randomized experiment** occurs when individual i is randomly assigned a **treatment**. A treatment is a set of explanatory variables corresponding to a row of \mathbf{X} .
- In a randomized experiment the independence assumption on the errors is reasonable: we can view the errors as coming from differences between individuals drawn independently from a large population.
- STATS 470 investigates design and analysis of experiments, which is an extension of linear statistical modeling.
- Random sampling removes selection bias, apart from missing data.
- STATS 480 investigates sample survey analysis, which also builds on linear statistical modeling.
